Chapter Introduction

In 1931, as the U.S. economy was suffering through the Great Depression, the New York Yankees paid famed baseball player Babe Ruth a salary of \$80,000. At the time, this pay was extraordinary, even among the stars of baseball. According to one story, a reporter asked Ruth whether he thought it was right that he made more than President Herbert Hoover, who had a salary of only \$75,000. Ruth replied, "I had a better year."

In 2010, the median salary earned by a player on the New York Yankees was \$5.5 million, and shortstop Alex Rodriguez was paid \$33 million. At first, this fact might lead you to think that baseball has become vastly more lucrative over the past eight decades. But as everyone knows, the prices of goods and services have also risen. In 1931, a nickel would buy an ice-cream cone, and a quarter would buy a ticket at the local movie theater. Because prices were so much lower in Babe Ruth's day than they are today, it is not clear whether Ruth enjoyed a higher or lower standard of living than today's players.

In the preceding chapter, we looked at how economists use gross domestic product (GDP) to measure the quantity of goods and services that the economy is producing. This chapter examines how economists measure the overall cost of living. To compare Babe Ruth's salary of \$80,000 to salaries from today, we need to find some way of turning dollar figures into meaningful measures of purchasing power. That is exactly the job of a statistic called the *consumer price index*. After seeing how the consumer price index is constructed, we discuss how we can use such a price index to compare dollar figures from different points in time.

The consumer price index is used to monitor changes in the cost of living over time. When the consumer price index rises, the typical family has to spend more money to maintain the same standard of living. Economists use the term *inflation* to describe a situation in which the economy's overall price level is rising. The *inflation rate* is the percentage change in the price level from the previous period. The preceding chapter showed how economists can measure inflation using the GDP deflator. The inflation rate you are likely to hear on the nightly news, however, is not calculated from this statistic. Because the consumer price index better reflects the goods and services bought by consumers, it is the more common gauge of inflation.

As we will see in the coming chapters, inflation is a closely watched aspect of macroeconomic performance and is a key variable guiding

macroeconomic policy. This chapter provides the background for that analysis by showing how economists measure the inflation rate using the consumer price index and how this statistic can be used to compare dollar figures from different times.

3 of 22

11-1 The Consumer Price Index

Ask the Author: Why do people continue to use CPI if it has an upward bias?				

The **consumer price index (CPI)** is a measure of the overall cost of the goods and services bought by a typical consumer. Each month, the Bureau of Labor Statistics (BLS), which is part of the Department of Labor, computes and reports the consumer price index. In this section, we discuss how the consumer price index is calculated and what problems arise in its measurement. We also consider how this index compares to the GDP deflator, another measure of the overall level of prices, which we examined in the preceding chapter.

11-1a How the Consumer Price Index Is Calculated

When the BLS calculates the consumer price index and the inflation rate, it uses data on the prices of thousands of goods and services. To see exactly how these statistics are constructed, let's consider a simple economy in which consumers buy only two goods: hot dogs and hamburgers. Table 1 shows the five steps that the BLS follows.

Step 1: Survey Consumers to Determine a Fixed Basket of Goods

Basket = 4 hot dogs, 2 hamburgers

Step 2: Find the Price of Each Good in Each Year

Year	Price of Hot Dogs	Price of Hamburgers	
2010	\$1	\$2	
2011	2	3	
2012	3	4	

Step 3: Compute the Cost of the Basket of Goods in Each Year

```
2010 ($1 per hot dog \times 4 hot dogs) + ($2 per hamburger \times 2 hamburgers) = $8 per basket
2011 ($2 per hot dog \times 4 hot dogs) + ($3 per hamburger \times 2 hamburgers) = $14 per basket
2012 ($3 per hot dog \times 4 hot dogs) + ($4 per hamburger \times 2 hamburgers) = $20 per basket
```

Step 4: Choose One Year as a Base Year (2010) and Compute the Consumer Price Index in Each Year

```
2010 ($8 / $8) × 100 = 100
2011 ($14 / $8) × 100 = 175
2012 ($20 / $8) × 100 = 250
```

Step 5: Use the Consumer Price Index to Compute the Inflation Rate from Previous Year

2011	$(175 - 100) / 100 \times 100 = 75\%$
2012	$(250 - 175) / 175 \times 100 = 43\%$

- 1. Fix the basket. Determine which prices are most important to the typical consumer. If the typical consumer buys more hot dogs than hamburgers, then the price of hot dogs is more important than the price of hamburgers and, therefore, should be given greater weight in measuring the cost of living. The BLS sets these weights by surveying consumers to find the basket of goods and services bought by the typical consumer. In the example in the table, the typical consumer buys a basket of 4 hot dogs and 2 hamburgers.
- 2. Find the prices. Find the prices of each of the goods and services in the basket at each point in time. The table shows the prices of hot dogs and hamburgers for three different years.
- 3. Compute the basket's cost. Use the data on prices to calculate the cost of the basket of goods and services at different times. The table shows this calculation for each of the three years. Notice that only the prices in this calculation change. By keeping the basket of goods the same (4 hot dogs and 2 hamburgers), we are isolating the effects of price changes from the effect of any quantity changes that might be occurring at the same time.
- 4. Choose a base year and compute the index. Designate one year as the base year, the benchmark against which other years are compared. (The choice of base year is arbitrary, as the index is used to measure changes in the cost of living.) Once the base year is chosen, the index is calculated as follows:

Consumer price index =
$$\frac{\text{Price of basket of goods and services in current year}}{\text{Price of basket in base year}} \times 100.$$

That is, the price of the basket of goods and services in each year is divided by the price of the basket in the base year, and this ratio is then multiplied by 100. The resulting number is the consumer price index.

In the example in the table, 2010 is the base year. In this year, the basket of hot dogs and hamburgers costs \$8. Therefore, the price of the basket in all years is divided by \$8 and multiplied by 100. The consumer price index is 100 in 2010. (The index is always 100 in the

base year.) The consumer price index is 175 in 2011. This means that the price of the basket in 2011 is 175 percent of its price in the base year. Put differently, a basket of goods that costs \$100 in the base year costs \$175 in 2011. Similarly, the consumer price index is 250 in 2012, indicating that the price level in 2012 is 250 percent of the price level in the base year.

5. *Compute the inflation rate*. Use the consumer price index to calculate the **inflation rate**, which is the percentage change in the price index from the preceding period. That is, the inflation rate between two consecutive years is computed as follows:

$$Inflation \ rate \ in \ year \ 2 = \frac{CPI \ in \ year \ 2 - CPI \ in \ year \ 1}{CPI \ in \ year \ 1} \times 100.$$

As shown at the bottom of Table 1, the inflation rate in our example is 75 percent in 2011 and 43 percent in 2012.

Although this example simplifies the real world by including only two goods, it shows how the BLS computes the consumer price index and the inflation rate. The BLS collects and processes data on the prices of thousands of goods and services every month and, by following the five foregoing steps, determines how quickly the cost of living for the typical consumer is rising. When the BLS makes its monthly announcement of the consumer price index, you can usually hear the number on the evening television news or see it in the next day's newspaper.

In addition to the consumer price index for the overall economy, the BLS calculates several other price indexes. It reports the index for specific metropolitan areas within the country (such as Boston, New York, and Los Angeles) and for some narrow categories of goods and services (such as food, clothing, and energy). It also calculates the **producer price index** (PPI), which measures the cost of a basket of goods and services bought by firms rather than consumers. Because firms eventually pass on their costs to consumers in the form of higher consumer prices, changes in the producer price index are often thought to be useful in predicting changes in the consumer price index.

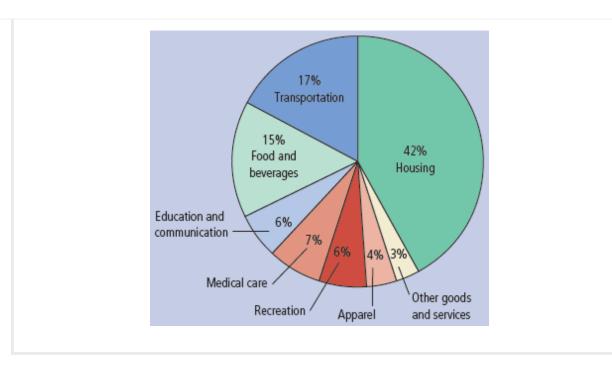

FYI: What Is in the CPI's Basket?

When constructing the consumer price index, the Bureau of Labor Statistics tries to include all the goods and services that the typical consumer buys. Moreover, it tries to weight these goods and services according to how much consumers buy of each item.

Figure 1 shows the breakdown of consumer spending into the major categories of goods and services. By far the largest category is housing, which makes up 42 percent of the typical consumer's budget. This category includes the cost of shelter (32 percent), fuel and other utilities (5 percent), and household furnishings and operation (5 percent). The next largest category, at 17 percent, is transportation, which includes spending on cars, gasoline, buses, subways, and so on. The next category, at 15 percent, is food and beverages; this includes food at home (8 percent), food away from home (6 percent), and alcoholic beverages (1 percent). Next are medical care, recreation, and education and communication, each at about 6 percent. This last category includes, for example, college tuition and personal computers. Apparel, which includes clothing, footwear, and jewelry, makes up 4 percent of the typical consumer's budget.

Figure 1. The Typical Basket of Goods and Services

This figure shows how the typical consumer divides spending among various categories of goods and services. The Bureau of Labor Statistics calls each percentage the "relative importance" of the category.

Also included in the figure, at 3 percent of spending, is a category for other goods and services. This is a catchall for consumer purchases (such as cigarettes, haircuts, and funeral expenses) that do not naturally fit into the other categories.

11-1b Problems in Measuring the Cost of Living

The goal of the consumer price index is to measure changes in the cost of living. In other words, the consumer price index tries to gauge how much incomes must rise to maintain a constant standard of living. The consumer price index, however, is not a perfect measure of the cost of living. Three problems with the index are widely acknowledged but difficult to solve.

The first problem is called *substitution bias*. When prices change from one year to the next, they do not all change proportionately: Some prices rise more than others. Consumers respond to these differing price changes by buying less of the goods whose prices have risen by relatively large amounts and by buying more of the goods whose prices have risen less or perhaps even have fallen. That is, consumers substitute toward goods that have become relatively less expensive. If a price index is computed assuming a fixed basket of goods, it ignores the possibility of consumer substitution and, therefore, overstates the increase in the cost of living from one year to the next.

Let's consider a simple example. Imagine that in the base year, apples are cheaper than pears, so consumers buy more apples than pears. When the BLS constructs the basket of goods, it will include more apples than pears. Suppose that next year pears are cheaper than apples. Consumers will naturally respond to the price changes by buying more pears and fewer apples. Yet when computing the consumer price index, the BLS uses a fixed basket, which in essence assumes that consumers continue buying the now expensive apples in the same quantities as before. For this reason, the index will measure a much larger increase in the cost of living than consumers actually experience.

The second problem with the consumer price index is the *introduction of new goods*. When a new good is introduced, consumers have more variety from which to choose, and this in turn reduces the cost of maintaining the same level of economic well-being. To see why, consider a hypothetical situation: Suppose you could choose between a \$100 gift certificate at a large store that offered a wide array of goods and a \$100 gift certificate at a small store with the same prices but a more limited selection. Which would you prefer? Most people would pick the store with greater variety. In essence, the increased set of possible choices makes each dollar more valuable. The same is true with the evolution of the economy over time: As new goods are introduced, consumers have more choices, and each dollar is worth more. Yet because the consumer price index is based on a fixed basket of goods and services, it does not reflect the increase in the value of the dollar that arises from the introduction of new goods.

Again, let's consider an example. When video cassette recorders (VCRs) were introduced in the late 1970s, consumers were able to watch their favorite movies at home. Although not a perfect substitute for a first-run movie on a large screen, an old movie in the comfort of your family room was a new option that increased consumers' set of opportunities. For any given number of dollars, the introduction of the VCR made

people better off; conversely, achieving the same level of economic well-being required a smaller number of dollars. A perfect cost-of-living index would have reflected the introduction of the VCR with a decrease in the cost of living. The consumer price index, however, did not decrease in response to the introduction of the VCR. Eventually, the BLS did revise the basket of goods to include VCRs, and subsequently, the index reflected changes in VCR prices. But the reduction in the cost of living associated with the initial introduction of the VCR never showed up in the index.

The third problem with the consumer price index is *unmeasured quality change*. If the quality of a good deteriorates from one year to the next while its price remains the same, the value of a dollar falls, because you are getting a lesser good for the same amount of money. Similarly, if the quality rises from one year to the next, the value of a dollar rises. The BLS does its best to account for quality change. When the quality of a good in the basket changes—for example, when a car model has more horsepower or gets better gas mileage from one year to the next—the Bureau adjusts the price of the good to account for the quality change. It is, in essence, trying to compute the price of a basket of goods of constant quality. Despite these efforts, changes in quality remain a problem because quality is so hard to measure.

There is still much debate among economists about how severe these measurement problems are and what should be done about them. Several studies written during the 1990s concluded that the consumer price index overstated inflation by about 1 percentage point per year. In response to this criticism, the BLS adopted several technical changes to improve the CPI, and many economists believe the bias is now only about half as large as it once was. The issue is important because many government programs use the consumer price index to adjust for changes in the overall level of prices. Recipients of Social Security, for instance, get annual increases in benefits that are tied to the consumer price index. Some economists have suggested modifying these programs to correct for the measurement problems by, for instance, reducing the magnitude of the automatic benefit increases.

In the News: Shopping for the CPI

Behind every macroeconomic statistic are thousands of individual pieces of data on the economy. This classic article follows one of the economists who collect these data.

In the Field with the Price Indexers

By Robert D. Hershey, Jr.

WILMINGTON, Del.—Her thick blue binder in hand, Diane Balaguer strides purposefully through the department store in the Concord Mall north of town. She checks the price of a women's pullover (short sleeve, solid color, no design), eyes a Hastings & Smith polo shirt, notes the seasonal absence of men's turtlenecks and then confronts the day's first challenge to statistical perfection.

Ms. Balaguer shakes her head slightly as she regards a rack of Towne raincoats, a style in the London Fog line (tagged at the same \$99.90 as the month before). She considers Towne to be of slightly, almost imperceptibly, lesser quality than the Severn line (costing about twice as much) that they replaced this year. it's a matter of things like stitching and buttons.

Earlier this spring she had informed specialists in Washington of this not uncommon situation but they overruled her suggestion that she substitute another product. Thus do tiny imprecisions creep unavoidably into the Consumer Price index, the most widely used inflation measure, one directly affecting the incomes of more than 70 million Americans, Federal income-tax brackets and the cost of school lunches.

"It's not a black-and-white sort of determination," Ms. Balaguer said. "Even though we ask very specific questions to try to get very specific answers, it takes a great deal of judgment."

When the price index is announced monthly by the Labor Department, the figure has the olympian air common to government statistics. But a day spent with Ms. Balaguer gives a vivid illustration of the messiness inherent in the immense task of monitoring changes in a \$7 trillion economy. in any given month, she and several hundred counterparts around the country check the cost of 90,000 items—ranging from catfish fillets to time spent in a hospital recovery room. . . .

A trained economist who both supervises data collection and often goes on the road herself, Ms. Balaguer expresses no opinion about the debate over the price index.

The system takes account of the possibility of human error or subversion—cross-checks of other data collectors' work is standard procedure. "We're taking our best shot," said Patrick C. Jackman, the index's chief day-to-day overseer in Washington. "i don't think we're picking up many bad quotes."

Drawing on an annual government survey of what people are buying, and at what kinds of outlets, headquarters tells the field staff what items to price. The findings are shipped by courier to Washington, where they are run through the mill to be sure they make sense. Because the bureau promises its respondents confidentiality, it insists that none of the 10 outlets Ms. Balaguer visits be identified by name. But she did disclose not only how prices in May compared with April's, but also explained in detail how to handle such vexations as discontinued products, clearance sales and what to do in those rare cases when she suspects somebody of giving wrong prices.

One of the day's most complicated readings came at a garden shop just across the state line in Pennsylvania where, after finding 3 1/2-inch barrel cactus and 16-inch Boston ferns unchanged in price (at \$4 and \$25, respectively) Ms. Balaguer found that the requisite flower seeds, black-eyed susans, were no longer being stocked.

After being told this was not just a temporary situation, Ms. Balaguer's solution was to find a substitute seed in the same product line to enter into the system on the spot. With the aid of a table in her binder that produces random numbers and with some rapid-fire pointing at rows of seed packets, the answer emerged in less than a minute. From now on, she declared, "we'll use pampas grass" in the index.

Not every hurdle was so quickly overcome. She spent a sizable chunk of her 20-minute session with a hospital administrator to figure out how to adjust for a confusing reconfiguration of recovery-room charges that effectively halved the price.

"You have to be able to ask questions, to be a sort of Sherlock Holmes," Ms. Balaguer said.

Ms. Balaguer's stop at a beer distributor to check one-liter bottles of Canada Dry seltzer caused some embarrassment when she questioned the assertion of Richard gropper, a proprietor, that the price was 84 cents. After she observed that this would mean a 9-cent rise from April he realized his mistake, adding that he was glad to help with the index since he periodically used it to adjust the rent of tenants in the doughnut shop next door.

The hardest items to price, Ms. Balaguer said, are electricity and natural gas, information the bureau gets directly from utilities in statistically awkward form. Children's meals and meals in Chinese restaurants also pose problems, even with menus to work from, because they tend to include beverages for which separate prices are required, Ms. Balaguer said.

Housing, which accounts for 41 percent of the urban consumer index, is surveyed by periodically questioning homeowners and renters. For both groups, the question is the same: What is the monthly rental value of the property? When necessary, such as when a house is vacant, she and her staff ask real estate brokers and neighbors to get housing data, Ms. Balaguer said.

Some surveyers might be bothered by one potentially onerous job restriction. But not Ms. Balaguer.

"We never carry purses because we're not allowed to shop while we work," she said. "Actually," she added, noting that she had originally worked in retailing, "I hate to shop."

New York Times, June 20, 1995.

11-1c The GDP Deflator versus the Consumer Price Index

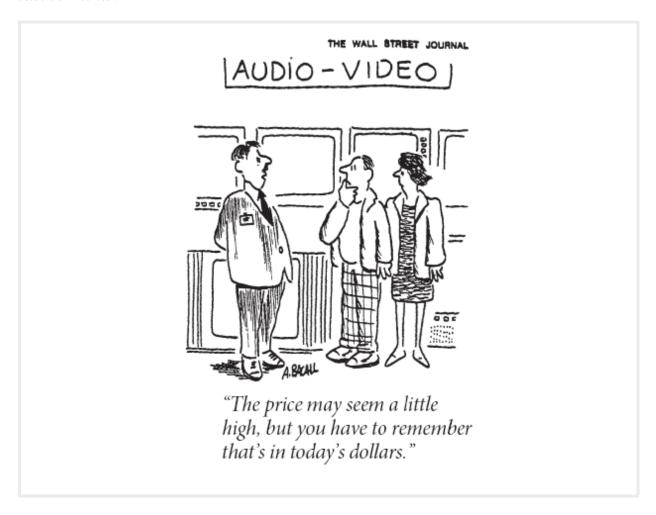

In the preceding chapter, we examined another measure of the overall level of prices in the economy—the GDP deflator. The GDP deflator is the ratio of nominal GDP to real GDP. Because nominal GDP is current output valued at current prices and real GDP is current output valued at base-year prices, the GDP deflator reflects the current level of prices relative to the level of prices in the base year.

Economists and policymakers monitor both the GDP deflator and the consumer price index to gauge how quickly prices are rising. Usually, these two statistics tell a similar story. Yet two important differences can cause them to diverge.

The first difference is that the GDP deflator reflects the prices of all goods and services *produced domestically*, whereas the consumer price index reflects the prices of all goods and services *bought by consumers*. For example, suppose that the price of an airplane produced by Boeing and sold to the Air Force rises. Even though the plane is part of GDP, it is not part of the basket of goods and services bought by a typical consumer. Thus, the price increase shows up in the GDP deflator but not in the consumer price index.

As another example, suppose that Volvo raises the price of its cars. Because Volvos are made in Sweden, the car is not part of U.S. GDP. But U.S. consumers buy Volvos, so the car is part of the typical consumer's basket of goods. Hence, a price increase in an imported consumption good, such as a Volvo, shows up in the consumer price index but not in the GDP deflator.

This first difference between the consumer price index and the GDP deflator is particularly important when the price of oil changes. Although the United States does produce some oil, much of the oil we use is imported. As a result, oil and oil products such as gasoline and heating oil are a much larger share of consumer spending than of GDP. When the price of oil rises, the consumer price index rises by much more than does the GDP deflator.

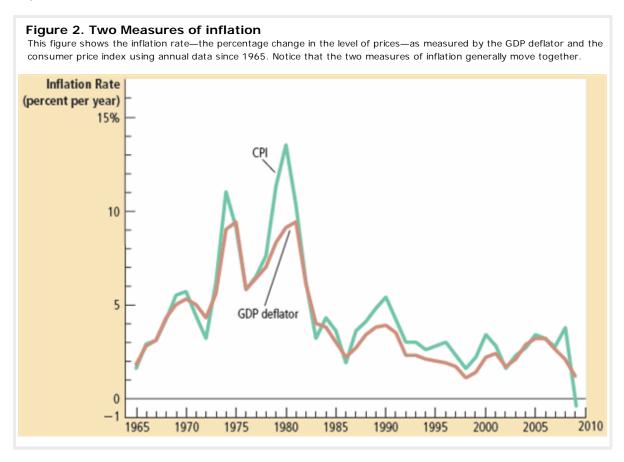

The second and subtler difference between the GDP deflator and the consumer price index concerns how various prices are weighted to yield a single number for the overall level of prices. The consumer price index compares the price of a *fixed* basket of goods and services to the price of the basket in the base year. Only occasionally does the Bureau of Labor Statistics change the basket of goods. By contrast, the GDP deflator compares the price of *currently produced* goods and services to the price of the same goods and services in the base year. Thus, the group of

7/10/2014 10:04 AM

goods and services used to compute the GDP deflator changes automatically over time. This difference is not important when all prices are changing proportionately. But if the prices of different goods and services are changing by varying amounts, the way we weight the various prices matters for the overall inflation rate.

Figure 2 shows the inflation rate as measured by both the GDP deflator and the consumer price index for each year since 1965. You can see that sometimes the two measures diverge. When they do diverge, it is possible to go behind these numbers and explain the divergence with the two differences we have discussed. For example, in 1979 and 1980, CPI inflation spiked up more than the GDP deflator largely because oil prices more than doubled during these two years. Yet divergence between these two measures is the exception rather than the rule. In the 1970s, both the GDP deflator and the consumer price index show high rates of inflation. In the late 1980s, 1990s, and the first decade of the 2000s, both measures show low rates of inflation.

QUICK QUIZ

Explain briefly what the consumer price index measures and how it is constructed. • Identify one reason why the CPI is an imperfect measure of the cost of living.

11-2 Correcting Economic Variables for the Effects of Inflation

The purpose of measuring the overall level of prices in the economy is to allow us to compare dollar figures from different times. Now that we know how price indexes are calculated, let's see how we might use such an index to compare a dollar figure from the past to a dollar figure in the present.

11-2a Dollar Figures from Different Times

We first return to the issue of Babe Ruth's salary. Was his salary of \$80,000 in 1931 high or low compared to the salaries of today's players?

To answer this question, we need to know the level of prices in 1931 and the level of prices today. Part of the increase in baseball salaries compensates players for higher prices today. To compare Ruth's salary to those of today's players, we need to inflate Ruth's salary to turn 1931 dollars into today's dollars.

The formula for turning dollar figures from year *T* into today's dollars is the following:

Amount in today's dollars = Amount in year
$$T$$
 dollars $\times \frac{\text{Price level today}}{\text{Price level in year }T}$

A price index such as the consumer price index measures the price level and thus determines the size of the inflation correction.

Let's apply this formula to Ruth's salary. Government statistics show a consumer price index of 15.2 for 1931 and 214.5 for 2009. Thus, the overall level of prices has risen by a factor of 14.1 (which equals 214.5/15.2). We can use these numbers to measure Ruth's salary in 2009 dollars, as follows:

Salary in 2009 dollars = Salary in 1931 dollars
$$\times$$
 $\frac{\text{Price level in 2009}}{\text{Price level in 1931}}$
= $\$80,000 \times \frac{214.5}{15.2}$
= $\$1,128,947$

We find that Babe Ruth's 1931 salary is equivalent to a salary today of over \$1 million. That is a good income, but it is less than a quarter of the median Yankee salary today and only 3 percent of what the Yankees pay A-Rod. Various forces, including overall economic growth and the increasing income shares earned by superstars, have substantially raised the living standards of the best athletes.

Let's also examine President Hoover's 1931 salary of \$75,000. To translate that figure into 2009 dollars, we again multiply the ratio of the price levels in the two years. We find that Hoover's salary is equivalent to \$75,000 × (214.5/15.2), or \$1,058,388, in 2009 dollars. This is well above President Barack Obama's salary of \$400,000. It seems that President Hoover did have a pretty good year after all.

11-2b Indexation

BBC Video: Core Index

As we have just seen, price indexes are used to correct for the effects of inflation when comparing dollar figures from different times. This type of correction shows up in many places in the economy. When some dollar amount is automatically corrected for changes in the price level by law or contract, the amount is said to be **indexed** for inflation.

For example, many long-term contracts between firms and unions include partial or complete indexation of the wage to the consumer price index. Such a provision is called a *cost-of-living allowance*, or COLA. A COLA automatically raises the wage when the consumer price index rises.

Indexation is also a feature of many laws. Social Security benefits, for example, are adjusted every year to compensate the elderly for increases in prices. The brackets of the federal income tax—the income levels at which the tax rates change—are also indexed for inflation. There are, however, many ways in which the tax system is not indexed for inflation, even when perhaps it should be. We discuss these issues more fully when we discuss the costs of inflation later in this book.

FYI: Mr. Index Goes to Hollywood

What is the most popular movie of all time? The answer might surprise you. Movie popularity is usually gauged by box office receipts. By that measure, *Avatar* is the number 1 movie of all time with domestic receipts of \$749 million, followed by *Titanic* (\$601 million) and *The Dark Knight* (\$533 million). But this ranking ignores an obvious but important fact: Prices, including those of movie tickets, have been rising over time. inflation gives an advantage to newer films.

When we correct box office receipts for the effects of inflation, the story is very different. The number 1 movie is now *Gone with the Wind* (\$1,606 million), followed by *Star Wars* (\$1,416 million) and *The Sound of Music* (\$1,132 million). *Avatar* falls to number 14.

"I see you don't like the effects of inflation."

Gone with the Wind was released in 1939, before everyone had televisions in their homes. in the 1930s, about 90 million Americans went to the cinema each week, compared to about 25 million today. But the movies from that era don't show up in conventional popularity rankings because ticket prices were only a quarter. And indeed, in the ranking based on nominal box office receipts, Gone with the Wind does not make the top 50 films. Scarlett and Rhett fare a lot better once we correct for the effects of inflation.

11-3 Real and Nominal Interest Rates

Correcting economic variables for the effects of inflation is particularly important, and somewhat tricky, when we look at data on interest rates. The very concept of an interest rate necessarily involves comparing amounts of money at different points in time. When you deposit your savings in a bank account, you give the bank some money now, and the bank returns your deposit with interest in the future. Similarly, when you borrow from a bank, you get some money now, but you will have to repay the loan with interest in the future. In both cases, to fully understand the deal between you and the bank, it is crucial to acknowledge that future dollars could have a different value than today's dollars. That is, you have to correct for the effects of inflation.

Let's consider an example. Suppose Sally Saver deposits \$1,000 in a bank account that pays an annual interest rate of 10 percent. A year later, after Sally has accumulated \$100 in interest, she withdraws her \$1,100. Is Sally \$100 richer than she was when she made the deposit a year earlier?

The answer depends on what we mean by "richer." Sally does have \$100 more than she had before. In other words, the number of dollars in her possession has risen by 10 percent. But Sally does not care about the amount of money itself: She cares about what she can buy with it. If prices have risen while her money was in the bank, each dollar now buys less than it did a year ago. In this case, her purchasing power—the amount of goods and services she can buy—has not risen by 10 percent.

To keep things simple, let's suppose that Sally is a movie fan and buys only DVDs. When Sally made her deposit, a DVD at her local movie store cost \$10. Her deposit of \$1,000 was equivalent to 100 DVDs. A year later, after getting her 10 percent interest, she has \$1,100. How many DVDs can she buy now? It depends on what has happened to the price of a DVD. Here are some examples:

- Zero inflation: If the price of a DVD remains at \$10, the amount she can buy has risen from 100 to 110 DVDs. The 10 percent increase in the number of dollars means a 10 percent increase in her purchasing power.
- Six percent inflation: If the price of a DVD rises from \$10 to \$10.60, then the number of DVDs she can buy has risen from 100 to approximately 104. Her purchasing power has increased by about 4 percent.
- Ten percent inflation: If the price of a DVD rises from \$10 to \$11, she can still buy only 100 DVDs. Even though Sally's dollar wealth has risen, her purchasing power is the same as it was a year earlier.
- Twelve percent inflation: If the price of a DVD increases from \$10 to \$11.20, the number of DVDs she can buy has fallen from 100 to approximately 98. Even with her greater number of dollars, her purchasing power has decreased by about 2 percent.

And if Sally were living in an economy with deflation—falling prices—another possibility could arise:

• Two percent deflation: If the price of a DVD falls from \$10 to \$9.80, then the number of DVDs she can buy rises from 100 to approximately 112. Her purchasing power increases by about 12 percent.

These examples show that the higher the rate of inflation, the smaller the increase in Sally's purchasing power. If the rate of inflation exceeds the rate of interest, her purchasing power actually falls. And if there is deflation (that is, a negative rate of inflation), her purchasing power rises by more than the rate of interest.

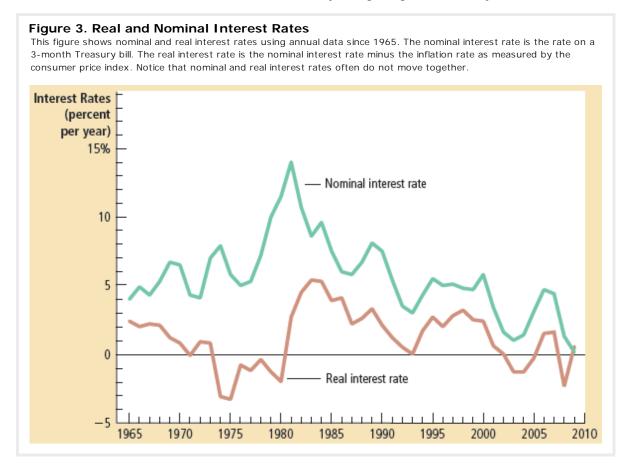

To understand how much a person earns in a savings account, we need to consider both the interest rate and the change in the prices. The interest rate that measures the change in dollar amounts is called the **nominal interest rate**, and the interest rate corrected for inflation is called the **real interest rate**. The nominal interest rate, the real interest rate, and inflation are related approximately as follows:

Real interest rate = Nominal interest rate - Inflation rate.

The real interest rate is the difference between the nominal interest rate and the rate of inflation. The nominal interest rate tells you how fast the number of dollars in your bank account rises over time, while the real interest rate tells you how fast the purchasing power of your bank account rises over time.

Case Study: Interest Rates in the U.S. Economy

Figure 3 shows real and nominal interest rates in the U.S. economy since 1965. The nominal interest rate in this figure is the rate on 3-month Treasury bills (although data on other interest rates would be similar). The real interest rate is computed by subtracting the rate of inflation from this nominal interest rate. Here the inflation rate is measured as the percentage change in the consumer price index.

One feature of this figure is that the nominal interest rate almost always exceeds the real interest rate. This reflects the fact that the U.S. economy has experienced rising consumer prices in almost every year during this period. By contrast, if you look at data for the U.S. economy during the late 19th century or for the Japanese economy in some recent years, you will find periods of deflation. During deflation, the real interest rate exceeds the nominal interest rate.

The figure also shows that because inflation is variable, real and nominal interest rates do not always move together. For example, in the late 1970s, nominal interest rates were high. But because inflation was very high, real interest rates were low. Indeed, during much of the 1970s, real interest rates were negative, for inflation eroded people's savings more quickly than nominal interest payments increased them. By contrast, in the late 1990s, nominal interest rates were lower than they had been two decades earlier. But because inflation was much lower, real interest rates were higher. In the coming chapters, we will examine the economic forces that determine both real and nominal interest rates.

QUICK QUIZ

Henry Ford paid his workers \$5 a day in 1914. If the consumer price index was 10 in 1914 and 218 in 2010, how much is the Ford paycheck worth in 2010 dollars?

11-4 Conclusion

"A nickel ain't worth a dime anymore," baseball player Yogi Berra once observed. Indeed, throughout recent history, the real values behind the nickel, the dime, and the dollar have not been stable. Persistent increases in the overall level of prices have been the norm. Such inflation reduces the purchasing power of each unit of money over time. When comparing dollar figures from different times, it is important to keep in mind that a dollar today is not the same as a dollar twenty years ago or, most likely, twenty years from now.

This chapter has discussed how economists measure the overall level of prices in the economy and how they use price indexes to correct economic variables for the effects of inflation. Price indexes allow us to compare dollar figures from different points in time and, therefore, get a better sense of how the economy is changing.

The discussion of price indexes in this chapter, together with the preceding chapter's discussion of GDP, is only a first step in the study of macroeconomics. We have not yet examined what determines a nation's GDP or the causes and effects of inflation. To do that, we need to go beyond issues of measurement. Indeed, that is our next task. Having explained how economists measure macroeconomic quantities and prices in the past two chapters, we are now ready to develop the models that explain movements in these variables.

Here is our strategy in the upcoming chapters. First, we look at the long-run determinants of real GDP and related variables, such as saving, investment, real interest rates, and unemployment. Second, we look at the long-run determinants of the price level and related variables, such as the money supply, inflation, and nominal interest rates. Last of all, having seen how these variables are determined in the long run, we examine the more complex question of what causes short-run fluctuations in real GDP and the price level. In all of these chapters, the measurement issues we have just discussed will provide the foundation for the analysis.

Chapter Recap: Summary

- The consumer price index shows the cost of a basket of goods and services relative to the cost of the same basket in the base year. The index is used to measure the overall level of prices in the economy. The percentage change in the consumer price index measures the inflation rate.
- The consumer price index is an imperfect measure of the cost of living for three reasons. First, it does not take into account consumers' ability to substitute toward goods that become relatively cheaper over time. Second, it does not take into account increases in the purchasing power of the dollar due to the introduction of new goods. Third, it is distorted by unmeasured changes in the quality of goods and services. Because of these measurement problems, the CPI overstates true inflation.
- Like the consumer price index, the GDP deflator measures the overall level of prices in the economy. The two price indexes usually move together, but there are important differences. The GDP deflator differs from the CPI because it includes goods and services produced rather than goods and services consumed. As a result, imported goods affect the consumer price index but not the GDP deflator. In addition, while the consumer price index uses a fixed basket of goods, the GDP deflator automatically changes the group of goods and services over time as the composition of GDP changes.
- Dollar figures from different times do not represent a valid comparison of purchasing power. To compare a dollar figure from the past to
 a dollar figure today, the older figure should be inflated using a price index.
- Various laws and private contracts use price indexes to correct for the effects of inflation. The tax laws, however, are only partially indexed for inflation.
- A correction for inflation is especially important when looking at data on interest rates. The nominal interest rate is the interest rate usually reported; it is the rate at which the number of dollars in a savings account increases over time. By contrast, the real interest rate takes into account changes in the value of the dollar over time. The real interest rate equals the nominal interest rate minus the rate of inflation.

Chapter Recap: Questions for Review

- 1. Which do you think has a greater effect on the consumer price index: a 10 percent increase in the price of chicken or a 10 percent increase in the price of caviar? Why?
- 2. Describe the three problems that make the consumer price index an imperfect measure of the cost of living.
- 3. If the price of a Navy submarine rises, is the consumer price index or the GDP deflator affected more? Why?
- 4. Over a long period of time, the price of a candy bar rose from \$0.10 to \$0.60. Over the same period, the consumer price index rose from 150 to 300. Adjusted for overall inflation, how much did the price of the candy bar change?
- 5. Explain the meaning of *nominal interest rate* and *real interest rate*. How are they related?

Chapter Recap: Problems and Applications

- 1. Suppose that the year you were born someone bought \$100 of goods and services for your baby shower. How much would you guess it would cost today to buy a similar amount of goods and services? Now find data on the consumer price index and compute the answer based on it. (You can find the BLS's inflation calculator here: http://www.bls.gov/data/inflation_calculator.htm (http://www.bls.gov/data/inflation_calculator.htm))
- 2. The residents of Vegopia spend all of their income on cauliflower, broccoli, and carrots. In 2010, they buy 100 heads of cauliflower for \$200, 50 bunches of broccoli for \$75, and 500 carrots for \$50. In 2011, they buy 75 heads of cauliflower for \$225, 80 bunches of broccoli for \$120, and 500 carrots for \$100.
 - a. Calculate the price of each vegetable in each year.
 - b. Using 2010 as the base year, calculate the CPI for each year.
 - c. What is the inflation rate in 2011?
- 3. Suppose that people consume only three goods, as shown in this table:

	Tennis Balls	Golf Balls	Bottles of Gatorade
2011 price	\$2	\$4	\$1
2011 quantity	100	100	200
2012 price	\$2	\$6	\$2
2012 quantity	100	100	200

- a. What is the percentage change in the price of each of the three goods?
- b. Using a method similar to the consumer price index, compute the percentage change in the overall price level.
- c. If you were to learn that a bottle of Gatorade increased in size from 2011 to 2012, should that information affect your calculation of the inflation rate? If so, how?
- d. If you were to learn that Gatorade introduced new flavors in 2012, should that information affect your calculation of the inflation rate? If so, how?
- 4. Go to the website of the Bureau of Labor Statistics (http://www.bls.gov (http://www.bls.gov)) and find data on the consumer price index. By how much has the index including all items risen over the past year? For which categories of spending have prices risen the most? The least? Have any categories experienced price declines? Can you explain any of these facts?
- 5. A small nation of ten people idolizes the TV show *American Idol*. All they produce and consume are karaoke machines and CDs, in the following amounts:

	Karaoke Machines		CDs	
	Quantity	Price	Quantity	Price
2011	10	\$40	30	\$10
2012	12	60	50	12

a. Using a method similar to the consumer price index, compute the percentage change in the overall price level. Use 2011 as the base year, and fix the basket at 1 karaoke machine and 3 CDs.

- b. Using a method similar to the GDP deflator, compute the percentage change of the overall price level. Also use 2011 as the base year.
- c. Is the inflation rate in 2012 the same using the two methods? Explain why or why not.
- 6. Which of the problems in the construction of the CPI might be illustrated by each of the following situations? Explain.
 - a. the invention of the iPod
 - b. the introduction of air bags in cars
 - c. increased personal computer purchases in response to a decline in their price
 - d. more scoops of raisins in each package of Raisin Bran
 - e. greater use of fuel-efficient cars after gasoline prices increase
- 7. The *New York Times* cost \$0.15 in 1970 and \$2.00 in 2009. The average wage in manufacturing was \$3.23 per hour in 1970 and \$20.42 in 2009.
 - a. By what percentage did the price of a newspaper rise?
 - b. By what percentage did the wage rise?
 - c. In each year, how many minutes does a worker have to work to earn enough to buy a newspaper?
 - d. Did workers' purchasing power in terms of newspapers rise or fall?
- 8. The chapter explains that Social Security benefits are increased each year in proportion to the increase in the CPI, even though most economists believe that the CPI overstates actual inflation.
 - a. If the elderly consume the same market basket as other people, does Social Security provide the elderly with an improvement in their standard of living each year? Explain.
 - b. In fact, the elderly consume more healthcare compared to younger people, and healthcare costs have risen faster than overall inflation. What would you do to determine whether the elderly are actually better off from year to year?
- 9. When deciding how much of their income to save for retirement, should workers consider the real or the nominal interest rate that their savings will earn? Explain.
- 10. Suppose that a borrower and a lender agree on the nominal interest rate to be paid on a loan. Then inflation turns out to be higher than they both expected.
 - a. Is the real interest rate on this loan higher or lower than expected?
 - b. Does the lender gain or lose from this unexpectedly high inflation? Does the borrower gain or lose?
 - c. Inflation during the 1970s was much higher than most people had expected when the decade began. How did this affect homeowners who obtained fixed-rate mortgages during the 1960s? How did it affect the banks that lent the money?

Chapter Recap: Key Terms

consumer price index (CPI)

a measure of the overall cost of the goods and services bought by a typical consumer

indexation

the automatic correction by law or contract of a dollar amount for the effects of inflation

inflation rate

the percentage change in the price index from the preceding period

nominal interest rate

the interest rate as usually reported without a correction for the effects of inflation

producer price index

a measure of the cost of a basket of goods and services bought by firms

real interest rate

the interest rate corrected for the effects of inflation

Chapter Recap: Highlights

Chapter Introduction

In the preceding chapter, we looked at how economists use gross domestic product (GDP) to measure the quantity of goods and services that the economy is producing. This chapter examines how economists measure the overall cost of living. To compare Babe Ruth's salary of \$80,000 to salaries from today, we need to find some way of turning dollar figures into meaningful measures of purchasing power. That is exactly the job of a statistic called the *consumer price index*. After seeing how the consumer price index is constructed, we discuss how we can use such a price index to compare dollar figures from different points in time.

11-1 The Consumer Price Index

The **consumer price index (CPI)** is a measure of the overall cost of the goods and services bought by a typical consumer. Each month, the Bureau of Labor Statistics (BLS), which is part of the Department of Labor, computes and reports the consumer price index. In this section, we discuss how the consumer price index is calculated and what problems arise in its measurement. We also consider how this index compares to the GDP deflator, another measure of the overall level of prices, which we examined in the preceding chapter.

11-1b Problems in Measuring the Cost of Living

Let's consider a simple example. Imagine that in the base year, apples are cheaper than pears, so consumers buy more apples than pears. When the BLS constructs the basket of goods, it will include more apples than pears. Suppose that next year pears are cheaper than apples. Consumers will naturally respond to the price changes by buying more pears and fewer apples. Yet when computing the consumer price index, the BLS uses a fixed basket, which in essence assumes that consumers continue buying the now expensive apples in the same quantities as before. For this reason, the index will measure a much larger increase in the cost of living than consumers actually experience.

11-1c The GDP Deflator versus the Consumer Price Index

The first difference is that the GDP deflator reflects the prices of all goods and services *produced domestically*, whereas the consumer price index reflects the prices of all goods and services *bought by consumers*. For example, suppose that the price of an airplane produced by Boeing and sold to the Air Force rises. Even though the plane is part of GDP, it is not part of the basket of goods and services bought by a typical consumer. Thus, the price increase shows up in the GDP deflator but not in the consumer price index.

••

The second and subtler difference between the GDP deflator and the consumer price index concerns how various prices are weighted to yield a single number for the overall level of prices. The consumer price index compares the price of a *fixed* basket of goods and services to the price of the basket in the base year. Only occasionally does the Bureau of Labor Statistics change the basket of goods. By contrast, the GDP deflator compares the price of *currently produced* goods and services to the price of the same goods and services in the base year. Thus, the group of goods and services used to compute the GDP deflator changes automatically over time. This difference is not important when all prices are changing proportionately. But if the prices of different goods and services are changing by varying amounts, the way we weight the various prices matters for the overall inflation rate.

11-2b Indexation

As we have just seen, price indexes are used to correct for the effects of inflation when comparing dollar figures from different times. This type of correction shows up in many places in the economy. When some dollar amount is automatically corrected for changes in the price level by law or contract, the amount is said to be **indexed** for inflation.

11-3 Real and Nominal Interest Rates

To understand how much a person earns in a savings account, we need to consider both the interest rate and the change in the prices. The interest rate that measures the change in dollar amounts is called the **nominal interest rate**, and the interest rate corrected for inflation is called the **real interest rate**. The nominal interest rate, the real interest rate, and inflation are related approximately as follows:
